Management of hypoxia during anaesthesia

**SpO₂ <94%**

Assume HYPOXIA until proven otherwise

Administer high flow oxygen
Consider hand ventilation with large tidal volumes

Probe on patient? Good waveform?

Yes

Is the problem with the patient?
Is the problem with the equipment?
Call for help if needed

**Check A B C D E**

No

Reposition probe
If necessary check probe on your own finger

Patient Problems

**AIRWAY**
Use chin lift/jaw thrust if using a mask
Reposition LMA if necessary
Check position of tracheal tube
If in doubt take LMA or tracheal tube out
Treat laryngospasm if present

**BREATHING**
Check adequate rate
Check adequate tidal volume
Check ET CO₂
Listen to both lungs
Bronchospasm? - consider bronchodilators
Pneumothorax? - consider chest drain

**CIRCULATION**
Check pulse
Check blood pressure
Check ECG
Blood loss / dehydration / fluid loss?
Consider IV fluid replacement

**DRUG EFFECTS**
Opioids
Volatile agent
Sedatives
Muscle relaxant
High spinal?

Equipment Problems

**EQUIPMENT**
Check oxygen supply / concentrator / cylinder
Check for breathing circuit disconnection
Check for breathing circuit obstruction

If problem not resolving:
Eliminate circuit - use self inflating bag

If self inflating bag not available consider:
Mouth to mouth / tracheal tube ventilation

If no pulse / BP / signs of life
Start CPR
Find and treat the cause

INTRODUCTION
Hypoxia during anaesthesia is common and is easily detected by a pulse oximeter. This article will describe how to respond to falling $\text{SpO}_2$.

COMMENTARY ON ALGORITHM

Causes of hypoxia during anaesthesia
The causes of hypoxia during anaesthesia are summarised in Table 1. Airway obstruction is the most common cause of hypoxia.

What should be done when the saturation falls?
During anaesthesia, low oxygen saturations must be treated immediately and appropriately. The patient may become hypoxic at any time during induction, maintenance or emergence from anaesthesia. The appropriate response is to administer 100% oxygen, make sure that ventilation is adequate by using hand ventilation and then correct the factor that is causing the patient to become hypoxic. For example, if the patient has an obstructed airway and is unable to breathe oxygen into the lungs, the problem will only be cured when the airway is cleared.

Table 1. Causes of hypoxia in theatre – consider ‘ABCDE’

<table>
<thead>
<tr>
<th>Source of problem</th>
<th>Common problem</th>
</tr>
</thead>
<tbody>
<tr>
<td>A. AIRWAY</td>
<td>• An obstructed airway prevents oxygen reaching the lungs</td>
</tr>
<tr>

</table>

Summary
During anaesthesia low oxygen saturations must be treated immediately.
Administer 100% oxygen.
Ventilate by hand, call for help and consider ‘ABCDE’.
Check for likely causes in a logical sequence.
Treat causes as you identify them.

Learning point:
When hypoxia occurs, it is essential to decide whether the problem is with the patient or the equipment. After a quick check of the common patient problems, make sure the equipment is working.
Whenever the patient has low saturations, administer high flow oxygen and consider ABCDE:

A - airway clear?
• Is the patient breathing quietly without signs of obstruction?
• Are there signs of laryngospasm? (mild laryngospasm – high pitched inspiratory noise; severe laryngospasm – silent, no gas passes between the vocal cords)
• Is there any vomit or blood in the airway?
• Is the tracheal tube in the right place?

Action
• Ensure that there is no obstruction. If breathing via a facemask - chin lift, jaw thrust,
• Consider an oropharyngeal or nasopharyngeal airway,
• Check for laryngospasm and treat if necessary.
• Check the tracheal tube/LMA - if any doubt about the position, remove and use a facemask.
• Suction the airway to clear secretions.

B - breathing adequately?
• Are there signs of laryngospasm? (mild laryngospasm – high pitched inspiratory noise; severe laryngospasm – silent, no gas passes between the vocal cords)

Action
• Consider waking the patient up if you have difficulty maintaining the airway immediately after induction of anaesthesia.
• Consider intubation.
• If you ‘can’t intubate, can’t ventilate’ an emergency surgical airway may be required (see page 15).

Airway obstruction is the most common cause of hypoxia in theatre. Airway obstruction is a clinical diagnosis and must be acted upon swiftly. Unrecognised inadvertent oesophageal intubation is a major cause of anaesthesia morbidity and mortality. An intubated patient who has been previously well saturated may become hypoxic if the tracheal tube becomes displaced, kinked or obstructed by secretions.

Check the endotracheal tube and - ‘If in doubt, take it out’.

C - circulation working normally?

B - Is the patient breathing adequately?

Look, listen and feel:
• Are the chest movements and tidal volume adequate?
• Listen to both lungs – is there normal bilateral air entry? Are the breath sounds normal? Any wheeze or added sounds?
• Is the chest movement symmetrical?
• Is anaesthesia causing respiratory depression?
• Is there a high spinal causing respiratory distress?

Bronchospasm, lung consolidation/collapse, lung trauma, pulmonary oedema or pneumothorax may prevent oxygen getting into the alveoli to combine with haemoglobin. Drugs such as opioids, poorly reversed neuromuscular blocking agents or deep volatile anaesthesia may depress breathing. A high spinal anaesthetic may paralyse the muscles of respiration. In an infant, stomach distension from facemask ventilation may splint the diaphragm and interfere with breathing. The treatment should deal with the specific problem.

Action
• Assist ventilation with good tidal volumes to expand both lungs until the problem is diagnosed and treated appropriately.
• If there is sufficient time, consider a chest X-ray to aid diagnosis.

The patient should be ventilated via a facemask, LMA or tracheal tube if the respiration is inadequate. This will rapidly reverse hypoventilation due to drugs or a high spinal and a collapsed lung will re-expand. The lower airway should be suctioned with suction catheters to remove any secretions. A nasogastric tube should be passed to relieve stomach distension.

A pneumothorax may occur following trauma, central line insertion or a supraclavicular brachial plexus block. It may be suspected if there is reduced air entry on the affected side. In thin patients a hollow note on percussion may also be detected. A chest X-ray is diagnostic but you should not delay treatment to wait for this. A chest drain should be inserted as the pneumothorax may worsen. When there is associated hypotension (tension pneumothorax), the pneumothorax should be treated by emergency needle decompression through the
2nd intercostal space in the mid-clavicular line without waiting for an X-ray. A definitive chest drain should be inserted later. Always maintain a high index of suspicion in trauma cases.

C - Is the circulation normal?

- Feel for a pulse and look for signs of life, including active bleeding from the surgical wound.
- Check the blood pressure.
- Check the peripheral perfusion and capillary refill time.
- Observe for signs of excessive blood loss in the suction bottles or wound swabs.
- Is anaesthesia too deep? Is there a high spinal block?
- Is venous return impaired by compression of the vena cava (gravid uterus, surgical compression).
- Is the patient in septic or cardiac shock?

Normally an inadequate circulation is revealed by the pulse oximeter as a loss or reduction of pulsatile waveform or difficulty getting a pulse signal.

**Action**

- If the blood pressure is low, correct it.
- Check for hypovolaemia.
- Give IV fluids as appropriate (normal saline or blood as indicated).
- Consider head down or leg up position, or in the pregnant mother, left lateral displacement.
- Consider a vasoconstrictor such as ephedrine or phenylephrine.
- If the patient has suffered a cardiac arrest, commence cardiopulmonary resuscitation (CPR) and consider reversible causes (4 H’s, 4T’s: Hypotension, Hypovolaemia, Hypoxia, Hypothermia; Tension pneumothorax, Tamponade (cardiac), Toxic effects (deep anaesthesia, sepsis, drugs), Thromboemboli (pulmonary embolism)).

D – Drug effects

Check that all anaesthesia drugs are being given correctly.

- Excessive halothane (or other volatile agent) causes cardiac depression.
- Muscle relaxants will depress the ability to breathe if not reversed adequately at the end of surgery.
- Opioids and other sedatives may depress breathing.
- Anaphylaxis causes cardiovascular collapse, often with bronchospasm and skin flushing (rash). This may occur if the patient is given a drug, blood or artificial colloid solution that they are allergic to. Some patients are allergic to latex rubber.

**Action**

- Look for an adverse drug effect.
- In anaphylaxis, stop administering the causative agent, administer 100% oxygen, give intravenous saline starting with a bolus of 10ml/kg, administer adrenaline and consider giving steroids, bronchodilators and an antihistamine.

E - Is the equipment working properly?

- Is there a problem with the oxygen delivery system to the patient?
- Does the oximeter show an adequate pulse signal?

**Action**

- Check for obstruction or disconnection of the breathing circuit or tracheal tube.
- Check that the oxygen cylinder is not empty.
- Check that the oxygen concentrator is working properly.
- Check that the central hospital oxygen supply is working properly.
- Change the probe to another site; check that it is working properly by trying it on your own finger.

If it is felt that the anaesthesia equipment is faulty, use a self-inflating bag to ventilate the patient with air while new equipment or oxygen supplies are obtained. If equipment is missing, mouth to tracheal tube, or mouth-to-mouth ventilation, may be lifesaving.

**CLINICAL SCENARIOS**

Work through problems in each case, deciding why the SpO$_2$ is low (ABCDE) and what the most appropriate action should be. The first three scenarios are explained in detail. The others should be discussed with your colleagues.

**Example 1**

A 12-year-old child is scheduled for elective anaesthesia for foot surgery. The patient is ASA 1 and is induced with thiopentone then given halothane in air and oxygen via a face mask. During the induction the patient starts to cough and gets laryngospasm. The SpO$_2$, which started at 98%, falls to 88% during coughing and then to 74% when laryngospasm occurs. Why has the saturation fallen and what would be the most appropriate actions?

- **Action**
  - Give 100% oxygen, assess ABCDE
  - A – airway obstruction due to laryngospasm; apply positive pressure to the reservoir bag, deepen anaesthesia. If the situation does not resolve, a small dose of suxamethonium (0.5mg/kg) should be given.
  - B – breathing improves after resolution of laryngospasm.
  - C – assess pulse rate - bradycardia may occur due to hypoxia or secondary to suxamethonium. Consider atropine after treating hypoxia.
  - D – check the halothane has not run out.
  - E – check that the anaesthesia equipment is functioning and connected appropriately.

After treating the laryngospasm, the patient improved and the SpO$_2$ returned to normal.
Example 2
A 56-year-old obese patient is undergoing a laparotomy for bowel obstruction. Preoperatively he is reasonably fit and his SpO₂ is 95%. After rapid sequence induction and intubation, the patient is ventilated and anaesthesia maintained using halothane in air with 30% oxygen. Over the next 10 minutes the patient’s SpO₂ falls to 85%. What are the most likely causes and what action would you take?

- Give 100% oxygen, check ABCDE.
- A – check the airway and position of the tracheal tube. Check there is equal air entry to both sides of the chest and that the tube is not kinked. Check that there is no vomit in the mouth to suggest that the patient may have aspirated.
- B – check that there are no added breath sounds to suggest aspiration, lung collapse or bronchospasm. Give large tidal volumes by hand and listed to the chest. Is ventilation easy?
- C – assess whether the circulation is normal.
- D – assess whether the patient is fully relaxed. Check that there are no signs to suggest drug reaction (particularly wheeze + hypotension + rash).
- E – check that the anaesthesia equipment is functioning and connected appropriately.

After ventilating the patient with some large tidal volumes and increasing the inspired oxygen the patient improved. The problem was lung collapse.

Example 3
During a caesarean section under spinal anaesthesia, a fit 23-year-old primigravida complains of tingling in the fingers and difficulty breathing. The SpO₂ falls from 97% to 88%. What are the most likely causes and what action would you take?

- Give 100% oxygen. Check ABCDE
- A – check that the airway is clear
- B - assess breathing. A high spinal may paralyse the muscles of respiration. If breathing is inadequate, ventilate the patient and induce anaesthesia and intubate. Ventilate until the block wears off.
- C – check the blood pressure – hypotension is likely. Treat with left lateral tilt, IV fluids and vasopressors.
- D – check the height of the block. Look for signs of a very high block - difficulty breathing, whispering rather than talking, weak arms and numbness on the shoulders. All indicate the nerves to the diaphragm are becoming blocked. This will make it impossible for the patient to breathe. If the block is not this high, the patient can talk in a normal voice and move their arms normally, but breathing still feels difficult due to the intercostal paralysis, normally the patient can breathe safely using their diaphragm.
- E – always ensure that equipment is ready in case this complication occurs.

After giving oxygen, the anaesthetist determined the block was not too high and the patient settled with reassurance. The SpO₂ improved with oxygen. Any hypoxia in a pregnant patient is dangerous.
